

MODERN
RADIOLOGY
eBook

Musculo- skeletal Imaging

ESR **RF** EUROPEAN SOCIETY
OF RADIOLOGY

/ Preface

Modern Radiology is a free educational resource for radiology published online by the European Society of Radiology (ESR). The title of this second, rebranded version reflects the novel didactic concept of the **ESR eBook** with its unique blend of text, images, and schematics in the form of succinct pages, supplemented by clinical imaging cases, Q&A sections and hyperlinks allowing to switch quickly between the different sections of organ-based and more technical chapters, summaries and references.

Its chapters are based on the contributions of over 100 recognised European experts, referring to both general technical and organ-based clinical imaging topics. The new graphical look showing Asklepios with fashionable glasses, symbolises the combination of classical medical teaching with contemporary style education.

Although the initial version of the **ESR eBook** was created to provide basic knowledge for medical students and teachers of undergraduate courses, it has gradually expanded its scope to include more advanced knowledge for readers who wish to 'dig deeper'. As a result, *Modern*

Radiology covers also topics of the postgraduate levels of the *European Training Curriculum for Radiology*, thus addressing postgraduate educational needs of residents. In addition, it reflects feedback from medical professionals worldwide who wish to update their knowledge in specific areas of medical imaging and who have already appreciated the depth and clarity of the **ESR eBook** across the basic and more advanced educational levels.

I would like to express my heartfelt thanks to all authors who contributed their time and expertise to this voluntary, non-profit endeavour as well as Carlo Catalano, Andrea Laghi and András Palkó, who had the initial idea to create an **ESR eBook**, and - finally - to the ESR Office for their technical and administrative support.

Modern Radiology embodies a collaborative spirit and unwavering commitment to this fascinating medical discipline which is indispensable for modern patient care. I hope that this **educational** tool may encourage curiosity and critical thinking, contributing to the appreciation of the art and science of radiology across Europe and beyond.

Minerva Becker, Editor

Professor of Radiology, University of Geneva, Switzerland

/ Musculoskeletal (MSK) Imaging Anatomy

Radiology is a fascinating specialty in medicine, dealing—by way of its diagnostic and interventional procedures—with not only recognition, but also treatment or palliation of abnormalities and diseases. The first known radiological image of human body from 22 December 1895 (**Figure 1**) is reportedly the hand radiograph of Anna Bertha Ludwig, the wife of the discoverer of X rays, Dr. Wilhelm Conrad Röntgen, who is considered to be the founder of radiology. This makes musculoskeletal imaging literally the first subspecialty in radiology!

Currently, musculoskeletal (MSK) radiologists use a wide array of ingenious techniques to diagnose—and sometimes treat—abnormalities and diseases in humans. Knowledge of musculoskeletal anatomy is essential in this context.

The **musculoskeletal (MSK) system** comprises bones, muscles, joints, subcutaneous tissue and distinct anatomic compartments, which play an important functional role.

/ Imaging Anatomy of Bones

All **long bones** comprise epiphysis, metaphysis, diaphysis—and sometimes apophysis (**Figures 2 and 3**).

Apophyses do not contribute to longitudinal growth and do not form a joint part as do the epiphyses.

The physes normally close during adolescence and no longer remain visible as radiolucent bands by the end of the second decade or the early years of the third decade of life.

FIGURE 2

Conventional radiographs illustrating parts of a long bone (here the femur) in a child and an adult.

The thickness of the bone cortex (or **cortical bone**) can vary among different bones and even within the same bone. It is usually thicker in the diaphysis.

The **bone medulla** (containing medullary bone or trabecular bone) comprises trabeculae, red and yellow marrow. The trabecular bone is also called “cancellous” bone.

Formerly referred to as growth “arrest” lines, growth “recovery” lines indicate periods of renewed or increased growth, presumably after a period of inhibited growth of the bone (Figure 4). They may, however, occur during normal growth and growth spurts.

FIGURE 4

Growth recovery lines (arrows on A) on MRI in a 4-year-old boy with resolved osteomyelitis elsewhere in this extremity. Growth recovery lines may occasionally present as curvilinear intra-epiphyseal silhouettes (arrowheads on B and C), giving the bone-within-bone appearance as in this 31-year-old woman, who sustained an ipsilateral femoral diaphyseal fracture at 10 years of age, whereupon she had had limited mobility for 6 months. Her other leg was unremarkable.

FIGURE 7

Chronic overuse injury at the tendo-osseous junctions of the proximal (A) and distal (B) aspects of the patellar tendon in two different 13-year-old boys (arrows).

/ Imaging Anatomy of Joints

Synovial joints (Figure 8) are surrounded by a capsule which is continuous with the periosteum of the articulating bones and sometimes formed by a continuum of collagen-rich structures such as ligaments, bands and tendons.

Some ligaments (e.g., anterior and posterior cruciate ligaments of the knee) and tendons (e.g., biceps long head tendon in the shoulder and popliteus tendon in the knee) are intraarticular.

Ligaments inside a joint are usually covered by synovium—joint-traversing tendons are usually not.

Some joints have specialised structures such as meniscus (knee), labrum (shoulder and hip) and triangular fibrocartilage complex (TFCC; wrist), which serve primarily as either buffer (menisci, TFCC) or deepen the socket-type joint (labra).

The most important component of a synovial joint is the **joint cartilage**, the loss of which is usually associated with a cascade of events leading to the dysfunction and destruction of a joint.

FIGURE 8

Although they do not provide cross-sectional information, radiographs are the **first-line imaging modality to study joints**. Cross-sectional examination of joints is best accomplished by magnetic resonance imaging

(MRI, see **Figure 9**), which gives the most comprehensive non-invasive information about not only the soft tissue components of a joint, but also the bones that form it.

Joint fluid estimation on radiographs

The knee is the largest joint in the human body. The suprapatellar recess (**Figure 9**) can be used for joint effusion assessment on radiographs. **Figure 10A** shows a normal suprapatellar recess (arrows) with a thickness ≤ 5 mm in a properly obtained lateral radiograph. **Figure 10B** shows a knee joint effusion with a distended suprapatellar recess (**arrows**). Also note the increased joint fluid tracks along the femoral trochlea (**arrowheads**), a feature not visible on **A**, where there is no joint effusion.

Suprapatellar recess distention with effusion can also be used to search for intra-articular fractures by taking advantage of the gravity-dependent layering of bone marrow fat and blood that flow into the joint space with such fractures (see Fractures and Dislocations>Pearls and Pitfalls in Identifying Fractures). Such use entails cross-table horizontal projection of X-rays to the image detector.

FIGURE 10

Lateral radiographs of a normal knee joint (**A**) and a joint with knee effusion (**B**).

/ Imaging Anatomy of Subcutaneous Tissue

Anatomists, surgeons and radiologists tend to use different terms to describe the components of the fascial system. The **radiological approach** is illustrated in **Figure 11**. Where muscles abut bones, the deep intermuscular fascia is in continuity with the periosteum. These structures are best depicted on MRI.

Interventional radiologists or oncologic orthopaedists perform tumour biopsies. It is best to make the biopsy at the medical centre where definitive surgery will be performed.

The **general principles for safe musculo-skeletal tumour biopsy** are (Figure 14):

- / Use the shortest path between skin and lesion
- / Avoid neurovascular and joint structures, lung, bowel, other organs
- / Needle path needs to be in the approximately same location where the incision for the definitive surgery will be made, so that the biopsy tract can be resected
- / Needle should not traverse an uninvolved or critical compartment, joint or neurovascular bundle

FIGURE 14

Axial MRI image. Femur (*). The **biopsy tract** for this expansile destructive distal femoral lesion not only should use the shortest path from the skin but also needs to avoid the undue contamination of the knee extensor mechanism (*the red route*), which, if the red route is used, would have to be considered contaminated (by tumour seeding) and resected during definitive surgery. The green route is to be preferred.

Test Your Knowledge

There are three distinct types of resolution in radiology (Figure 15). Imaging modalities vary in their advantages on any given type of resolution.

Spatial resolution

Ability to discern **closeness in space** of two adjacent pixels

Better:
As small a pixel size as possible

Conventional radiographs and CT have excellent spatial resolution, which, however, is not equally matched with contrast resolution.

Contrast resolution

Ability to discern **structural variations of different pixels**

Better:
As subtle a pixel variation as possible

MRI has excellent contrast resolution, which, however, is not usually equally matched with spatial resolution. US has very good contrast and spatial resolution.

Temporal resolution

Ability to discern **pixel differences over time**

Better:
As short a time period as possible

Especially important in dynamic contrast-enhanced studies. Digital angiography and real-time fluoroscopy have excellent temporal resolution.

FIGURE 15

Differences between spatial, contrast and temporal resolution.

/ Conventional Radiographs (CRX): Five Shades of Grey

Although not capable of giving cross-sectional information, radiographs are the **first-line imaging tool** in the MSK system. Radiographs feature five basic shades of grey, depending on the density (or X-ray attenuation) of the content imaged (**Figure 16**).

FIGURE 16

Basic grey shades on conventional radiographs (CRX).

>|< COMPARE

PROS

- + Easy
- + Inexpensive

CONS

- Not cross-sectional
- Ionising radiation

COSTS

Radiographs << US < CT < MRI

<!=> ATTENTION

Don't be surprised to see that muscles are of water density (they contain abundant water)!

Note that subcutaneous fat is of intermediate density between ambient air and muscles (mostly water), which makes sense, because fat is less dense than water, but denser than air.

Three-dimensional rendering of bone lesions is another advantage of CT (A), enabling orthopaedic surgeons to better visualise what they will encounter during surgery as in this 23-year-old woman with osteo-chondromatosis (arrows). B is one of the source images.

/ Ultrasonography (US): Great Soft Tissue Detail, No Ionising Radiation

US is capable of giving real-time cross-sectional information without any ionising radiation and can be used for interventional procedures (Figures 21 and 22).

>|< COMPARE

PROS

- + Easy for the patient
- + Relatively inexpensive
- + No ionising radiation
- + Dynamic exam feasible
- + Doppler mode shows vascularity
- + Can be used for guidance in some procedures (e.g., soft tissue lesion biopsy, barbotage for calcific tendonitis)

CONS

- Does not show bones
- Deep soft tissues are usually beyond the scope of ultrasound probe for subtle lesions
- Operator-dependent
 - ^ This means that significant expertise is needed to be able to identify and characterise MSK soft tissues

FIGURE 21

Shoulder US shows a focal full-thickness tear (asterisk) of the supraspinatus (SS) tendon at its insertion near the humeral head (H).

/ MR-/CT-Arthrography: A Special Method in MSK Imaging

Cross-sectional imaging mostly with MRI (sometimes with CT) following intraarticular injection of contrast material is occasionally used to better delineate small structures within joints (**Figures 26 and 27**).

The injected contrast not only distends the joint space but also dilutes the joint fluid, making it possible for the otherwise somewhat viscous joint fluid to enter the nooks and crannies and disclose tears.

FIGURE 26

MR-arthrography (**B**) after intraarticular injection of contrast material into the left hip joint under fluoroscopy guidance (**A**) showed a tear at the base of the anterior acetabular labrum (**arrow**).

FIGURE 27

This patient had a cardiac defibrillator (**D**) and could not undergo MRI. Injection of contrast material under fluoroscopic guidance (**A**) and CT-arthrography (**B**) showed a tear (**arrow**) of the infrapatellar tendon filling with the intraarticularly injected contrast material.

General Principles

One of the main tasks while dealing with arthropathy in a patient is to decide whether it is degenerative (e.g., osteoarthritis) or inflammatory (e.g.,

rheumatoid arthritis). Pathophysiologic mechanisms and therefore imaging findings in these two main conditions are quite different (**Figure 28**).

Normal joint

Bare areas of the bone (*) are within the joint space but not covered with joint cartilage.

Osteoarthritis

Bones rub against each other with non-uniform loss of joint cartilage. Osteophytes attempt to stabilise the joint. Subchondral sclerosis is a stress response to cartilage loss and mechanical imbalance. Cysts may occur.

Rheumatoid arthritis

Synovial inflammation first erodes bare areas and later expands inside and outside the joint. As the disease progresses, the loss of joint cartilage is usually uniform, resulting in an evenly narrowed joint space on radiographs.

FIGURE 28

Schematic illustration of the differences between osteoarthritis and rheumatoid arthritis.

/ Osteoarthritis: The Hallmark of Degenerative Joint Disease

Osteoarthritis is the most common joint disease. Characteristic radiographic features (**Figure 29**) are asymmetric (non-uniform) joint space narrowing (due to joint cartilage loss) with osteophytes, bone

sclerosis and subchondral cysts in the absence of such inflammatory features as erosions. Synovitis and osteitis, however, can be seen in osteoarthritis..

FIGURE 29

Anteroposterior radiograph showing right > left hip osteoarthritis in a 64-year-old woman (hips enlarged in **B** and **C**). Characteristic features include non-uniform narrowing of the joint space, subchondral sclerosis (**black arrowhead**) and cysts (**arrows**) and marginal osteophytes (**white arrowheads**).

/ Osteoarthritis: Primary and Secondary

Primary (idiopathic) osteoarthritis is the more common form of the disease and occurs without a prior insult (**Figure 30**), which is the characteristic of secondary osteoarthritis. Crystal deposition, inflammatory arthritis and other synovial disease,

trauma, infection, developmental dysplasia and impingement syndromes can all lead to **secondary osteoarthritis** (**Figures 31 and 32**), whereby imaging can help establish the background.

<=> ATTENTION

Bones in the hands, wrists, feet and ankles make up slightly more than half of all bones in the human body and the respective joints account for one third of all our articulations. It should therefore come as no surprise that distal aspects of our extremities are extensively examined in the work-up of arthritis.

FIGURE 30

Primary osteoarthritis manifestations in a 59-year old woman include non-uniform narrowing, subchondral cysts and marginal osteophytes at the distal interphalangeal, first carpometacarpal and scaphoid-trapezium joints (**yellow arrows**). Secondary osteoarthritis in the form of calcium pyrophosphate dihydrate deposition (CPPD) arthropathy is also evident at the right second and third and left first metacarpophalangeal (MCP) joints with hook osteophytes in the distal metacarpals (**white arrows**) and right second MCP joint cartilage calcification (**pink arrow**).

FIGURE 43

Lumpy-bumpy appearance due to tophi around joints and periarticular erosions with overhanging edges (A), tarsometatarsal joint erosions (ellipses and arrowheads) on foot radiograph (B) and CT (C and D) are typical imaging findings of gout. Note the distal tophus along the anterior tibial tendon (arrows).

Calcium Pyrophosphate Dihydrate (CPPD) Arthropathy

Although gout is considered as the hallmark of metabolic arthritis, CPPD is more common than gout, given the fact that it is usually seen in an older age group and that humans have increased longevity. In fact, CPPD arthropathy is more common than rheumatoid

arthritis – and second, in frequency, only to osteoarthritis. Characteristic findings are shown in **Figure 44**.

FIGURE 44

CPPD arthropathy in a 94-year old woman. Second and third metacarpophalangeal (MCP) joint arthritis (ellipses), hook osteophytes along radial aspects of second and third distal metacarpals (arrows), calcification at the triangular fibrocartilage (pink arrowhead), scapholunate ligament (green arrowhead) and third MCP joint cartilage (yellow arrowhead).

>=< FURTHER KNOWLEDGE

Interestingly, CPPD arthropathy can present without visible calcifications within joints. Involvement of the characteristic locations (MCP joints and radiocarpal compartment, both of which are unusual locations for primary osteoarthritis) along with second and third distal metacarpal hook osteophytes in a patient >50 years would be clues to CPPD arthropathy, even in the absence of intraarticular calcifications on imaging.

/ Basic Principles in Imaging Fractures and Dislocations

- / **More than one radiographic projection** is needed for any part of the body.
- / Although radiographs are the first-line imaging tool to look for fractures and/or dislocations, CT is more appropriate in body parts with complex anatomy (e.g., face, thoracic cage, pelvis).
- / **Two radiographic projections** perpendicular to each other need to be used for extremity segments (i.e., arm, forearm, thigh and calf; **Figure 47**).
- / **Three radiographic projections** (anteroposterior/postero-anterior, lateral, oblique) are recommended for most joints (e.g., wrist, hand, ankle, foot).
- / Stress radiographs (e.g., scaphoid view for suspected fracture of this wrist bone) or additional projections (e.g., axillary view and/or Y-view in the shoulder) can be used in some joints and certain conditions.
- / Radiographs need to cover the joints adjacent to a long bone (**Figure 47**); if a single X-ray detector plate does not suffice to include joints at both ends, two acquisitions are needed for each projection.
- / Due to the ongoing ossification in children, comparative radiographs

/ Fractures: Terminology

There are many ways to describe a fracture depending on its properties (**Figures 51** and **52**). Based on the **orientation or shape** of the fracture line, a fracture can be described as transverse, oblique or spiral. **Avulsion** fractures happen at the insertion sites of tendons or

ligaments, due to their sudden pull. Sometimes fracture fragments override each other or one fracture fragment impacts onto another. **Impaction** fractures in the spine are called vertebral collapse; there might be retropulsion of the fracture fragments narrowing the spinal canal and compromising its contents.

Test Your Knowledge

When a fracture is comminuted, open or intraarticular (**Figure 52**), management is more difficult. Imaging makes it possible to identify such fractures.

Comminuted fracture

Radiographs show three or more fragments in a fracture. Small fracture pieces are called “butterfly fragments” due to their similarity to butterfly wings.

Metallic opacities at the fracture site in this patient are bullet fragments.

Open fracture

The skin is disrupted and at least one of the fracture fragments is exposed to the outside. By default, they are considered contaminated. A splint is in place on this patient.

Intraarticular fracture

The fracture extends into a joint. Intra-articular fractures usually require surgery. Gap (**red double arrow**) or step-off between fracture fragments at the articular surface or fragments within joint space are searched with radiographs – or better with CT. Fragments (**red arrow**) within the joint space need to be removed, otherwise they would damage the intact joint cartilage. When an impacted fracture fragment (**area outlined in red**) is present, bone grafting may be necessary.

/ Fractures: Stress (Load) Versus Strain (Deformation)

The stress-strain curve for any material (**Figure 53**) displays the relationship between the amount of load it can absorb and the deformation it can tolerate before reaching its yield point and ultimately its failure point.

Figure 54 illustrates the effects of

non-reversible deformation on the fibula and tibia, passing the yield and failure points, respectively.

FIGURE 53

Drawing adapted from Pathria M et al. Radiology 2016.

>< FURTHER KNOWLEDGE

FIGURE 54

Comminuted fracture of the tibial diaphysis in this 17-year-old boy, who was shot at, shows butterfly fragments. The paperclip is used to mark the bullet entry site. No exit site is marked because the bullet hit the tibia, fractured it and was then dispersed into the calf muscles (*presumed path of the bullet is shown with dashed arrows on the lateral radiograph below*). The fibula is bowed ("plastic bowing deformity"). Since the ossification is not yet complete in this boy, the fibula could be bent back into its normal shape during reduction of the tibial fracture, which was then fixed with an intramedullary nail and locking screws (right). The fibula was in the "plastic region" on the graph at far left, while the tibia had already passed beyond this region. Note that a drain (D) and a splint (S) are in place post-operatively (right). Also note that the bullet fragments have not been removed during surgery, which would have violated the first principle of medicine.

/ Fractures in Children: Special Features

The growing skeleton in children presents challenges and opportunities to detect fractures. Some fracture types, such as **greenstick** and **torus (buckle) fractures**, are almost exclusively seen in children (**Figure 55**). Tendons and ligaments are quite strong in children, whereas the

tensile strength of their attachment sites in bones are not equally up to task; therefore avulsion fractures, too, are more common in children (**Figure 56**). The orderly appearance of ossification centres around the elbow can be used to detect fractures in children before their teens (**Figure 57**).

FIGURE 55

Difference between greenstick fracture and torus fracture. In greenstick fracture, the side opposite the bending force fractures completely, whereas the side under the force can remain intact (**green arrows**). The torus fracture is an impaction fracture in which the cortex around all or part of the bone circumference is buckled (**red arrows**).

FIGURE 56

Avulsion fracture of the tibial eminence at the attachment site (**pink arrow**) of the anterior cruciate ligament (**asterisk**) in a 12-year-old girl.

>=< FURTHER KNOWLEDGE

FIGURE 57

Using the orderly appearance of ossification centres to detect elbow fractures in children. Ossification centres around the elbow (drawings) follows this order: capitulum, radial head, internal (medial) epicondyle, trochlea, olecranon, lateral epicondyle (mnemonic: CRITOL). Therefore, what appears to be the lateral epicondyle (arrowhead on the CRX) in this 6-year-old boy with a capitellar fracture (arrow) has to be an additional avulsion fracture. Because, although the radial head (R) and internal epicondyle (I), as well as the capitellum (C) have already appeared, the trochlea is not yet visible.

/ Stress Fractures

“Stress fractures” occur without major (i.e., high-energy) trauma during daily activities due to a mismatch between repetitive mechanical stress and bone strength. Stress fractures are usually seen in the lower extremities or the spine. There are two types of stress fractures:

FIGURE 61

A. MRI shows right>left femoral neck incomplete fatigue fractures (arrows) surrounded by bone marrow oedema in an otherwise healthy 9-year-old basketball player. **B.** Follow-up MRI seven months later shows disappearance of fractures and complete resolution of marrow oedema.

- / Fatigue fracture (overuse fracture) is caused by abnormal stress or abnormally strenuous activity on a normal bone. The continuous application of an increased stress (e.g., running) in a normal body can cause microfractures. When they accumulate faster than the body can heal, these microfractures eventually give way to macroscopic failure (an overt stress fracture) visible on imaging (**Figure 61**).
- / Insufficiency fracture is caused by normal stress on abnormal bone, e.g., associated with vitamin D deficiency or osteoporosis (**Figure 62**).

FIGURE 62

MRI shows a subcortical incomplete insufficiency fracture (arrow) surrounded with bone marrow oedema (*) at the weight-bearing portion of the medial femoral condyle in this 65-year-old woman with osteoporosis. The posterior root avulsion of the degenerated medial meniscus (arrowheads) resulted in medial meniscus extrusion, likely paving the way for this fracture. A small amount of stress during normal daily activities is sufficient to cause such a fracture in the background of osteoporosis.

FIGURE 65

Pelvis radiograph (A) and MR images (B-D) show a right femoral neck fracture that occurred in the background of a metastatic lesion (arrows) in this 53-year-old woman with breast cancer. Other metastases are marked by arrowheads.

/ Pearls and Pitfalls in Identifying Fractures

We use a systematic approach to look for fractures on radiographs, making use of some pearls. All along, we need to take into account also some pitfalls so as not to misidentify a fracture.

Cortices of all bones on radiographs need to be followed. When there is a break in the cortical continuity, there might be a fracture (**Figure 66**).

FIGURE 66

This 65-year-old woman slipped on ice and fell onto her outstretched hand. The breaks in cortical continuity of the distal radius (**white arrows**) represent a fracture, later confirmed by MRI (**red arrows**), which also showed both the bone marrow and soft tissue oedema (*).

<=> ATTENTION

Following cortical continuity on radiographs is essential.

MRI is the best modality to show an **acute fracture** (chronic fractures and tiny intraarticular fracture fragments, however, might be easily missed on MRI). There is a simple reason for this: Two things always happen in an acute fracture (even if it is an incomplete fracture): Bone marrow oedema surrounding the fracture line and soft tissue oedema at the immediate vicinity of the fracture. MRI is the only imaging modality to show both of these exquisitely. When a fracture is not visible on radiographs but identified on MRI (or sometimes on CT), it is called an **occult fracture**.

/ Pearls in Identifying Fractures

<=> ATTENTION

Looking for soft tissue oedema on radiographs. Zooming and changing brightness and contrast settings.

ESSENTIAL

The close vicinity of soft tissue oedema on radiographs is a prime suspect area for acute fractures. All radiographs need to be scrutinised by zooming and changing brightness and contrast settings. Acute fractures are always associated with surrounding soft tissue oedema (Figures 67 and 68). Not all soft tissue oedema, however, is necessarily associated with fractures.

FIGURE 67

The only clinical information given to the radiologist about this patient was "pain". CRX of the calf (A) and zoomed detail (B and C). Careful examination of the subcutaneous fat density reveals oedema (water density) overlying the medial ankle (arrowheads). Note that there is an incomplete fracture (arrow) underlying the soft tissue oedema. The fracture is better appreciated on a different brightness and contrast setting (arrow, C). It was later confirmed with the patient that her pain was indeed in this location.

Lipohaemarthrosis

> Telltale sign of an intraarticular fracture

When a fracture extends into a joint, fat and blood from the bone marrow flow into the joint space (and its recesses), hence the name "lipohaemarthrosis". Gravity-dependent layering of fat, serum and haematocrit can be seen by sending a horizontal beam through the joint and picking up these "cross-table" X-rays on a detector plate (Figure 69).

FIGURE 69

Intraarticular extension of the proximal tibial fracture (**dashed arrow**) in this patient was ascertained by the use of cross-table radiographic technique showing layering (**solid arrows**) of bone marrow fat and blood within the suprapatellar recess of the knee.

Blood and fat from the bone marrow of the fractured proximal tibia filling the suprapatellar recess.

Radiographic appearance of the layered bone marrow fat-serum-haematocrit filling the suprapatellar recess.

Acute Fracture versus Old Fracture

One of the hallmarks of an acute fracture is the lack of cortical bone at the fracture edges opposing each other. Over time cortication of ununited fracture fragments occurs. This is an important distinction for estimating fracture age (acute versus old) as shown in **Figures 71** and **72**.

FIGURE 71

Note the non-white (i.e., uncorticated) and craggy edges at the opposing surfaces of fracture fragments in this coracoid fracture (**circle**, left; **arrow**, right).

FIGURE 72

Compare the uncorticated edges at the opposing surfaces of fracture fragments in this comminuted intra-articular fracture of the fifth metacarpal base (**circles**) with the corticated old fracture of the hook of the hamate (**arrows**).

<!> ATTENTION

Beware of “satisfaction of search”!

The hardest fracture to find is “the next one”. This means, even if we find a fracture (or another one), we do not stop there and carry on our systematic search, as other fractures might be lurking somewhere on the images (Figure 73).

**FIGURE 73**

Comminuted fracture of the tibia diaphysis is easily identified in this patient. The fracture of the proximal fibula, (arrows, enlarged views on the right), however, was missed.

/ Pitfalls of Fractures: Skin Folds, Intra-articular Gas, Physeal Lines, Nutrient Vessels

- / A skin fold or intraarticular gas might sometimes be mistaken for a fracture (**Figure 74**).
- / A physeal line around the time of its closure can also mimic a fracture (**Figure 74**).
- / Another common mimicker of fractures is a nutrient vessel (**Figure 75**).

FIGURE 74

Skin fold (white arrows), intra-articular gas (red arrow) and physeal lines (arrowhead) mimicking fractures.

FIGURE 75

Nutrient vessel (white arrows, top left) mimicking a fracture on CRX. CT clearly shows that this appearance is caused by a nutrient vessel (green arrows).

/ “Don’t Touch” Lesions

<!=> ATTENTION

These are benign lesions where a radiological diagnosis is made without a differential diagnosis list and biopsy is NOT to be performed (it is unnecessary, may be misleading and may even lead to unnecessary surgery).

>=< FURTHER KNOWLEDGE

“Don’t touch” lesions include:

- / Fibrous cortical defect (Figure 91)
- / Non-ossifying fibroma (Figure 91)
- / Bone island (Figure 91)
- / Bone infarct (Figure 91)
- / Solitary bone cyst (Figure 91)
- / Distal femoral cortical irregularity (Figures 92 and 93)
- / Myositis ossificans (Figure 94)

FIGURE 91

The self-explanatory fibrous cortical defect (A) is called non-ossifying fibroma (NOF) when it is > 2cm (B) and features lobulated contours (arrows). These are usually incidental. NOF may be slightly expansile. Bone island (C) presents as a hyperdense (sclerotic) lesion with spiculated contours (arrow). Bone infarcts (D) are heterogeneously sclerotic lesions with geographic contours. Solitary bone cyst (E) presents as a well defined radiolucency. The “fallen fragment” sign denotes pathological cortical fracture fragment(s) that are displaced into the cyst (arrows).

FIGURE 103

Examples of characteristic imaging findings in some bone tumours

/ Radiology of Soft Tissue Tumours

On imaging, a soft tissue mass with well-defined margins is **not necessarily** benign. Smaller (≤ 5 cm) and superficial (versus deep-seated) lesions are more likely benign. Ganglion cysts and lipomas are the most common soft tissue masses. Ultrasonography is useful in discriminating solid versus cystic lesions and further characterising some solid lesions. The best combination of "MRI plus radiographs" provides specific diagnosis in only about 30%–50% of cases.

MRI is the modality of choice to show compartmental involvement, which is important in staging and to plan the route for biopsy, which is usually performed under US or CT guidance. Examples of soft tissue tumours as seen on MRI are shown in **Figure 104**.

/ Radiology of Soft Tissue Tumours

For subcutaneous lesions, **relation with the peripheral muscular fascia** (see **Figure 11**) is important. While a preserved fascial plane between a subcutaneous mass lesion and the peripheral fascia is no guarantee of a benign histology, fascial violation by the mass lesion is a clear sign of aggressive behaviour (**Figure 105**). MRI is the best imaging modality in the follow-up of malignant

soft tissue masses (**Figure 106**). Some properties of mass lesions such as internal haemorrhage or melanin content can also be identified on MRI (**Figure 107**).

FIGURE 105

Violation of the peripheral fascia (arrows) is a clear sign of malignancy in this myxofibrosarcoma.

FIGURE 106

This patient was operated on for a subcutaneous mass that turned out to be an undifferentiated pleomorphic sarcoma (not shown). Postsurgical changes are evident in the first MRI shortly after surgery (arrow, A). Ten weeks later, a new soft tissue mass was identified (arrow, B), which was excised and confirmed to be local recurrence. Follow-up MRI four months later (C) was free of neoplastic masses.

FIGURE 107

Arrows point to some of the extensive haemorrhagic calf muscle metastases from an alveolar soft part sarcoma in this special MRI sequence called “susceptibility-weighted imaging”. Within the MRI machine, which features a strong magnetic field, the paramagnetic property of iron content from hemosiderin (due to haemorrhage) makes these so-called “blooming” artifacts (arrows) and thereby highlights bleeding.

/ Osteoporosis: The Most Common Metabolic Bone Disease

Osteoporosis is characterised by diminished but otherwise normal bone. It may be a local phenomenon (e.g., disuse osteoporosis, **Figure 108**) as well as a generalised condition (**Figure 109**). The World Health

Organization defines osteoporosis as a dual-energy X-ray absorptiometry-based (DEXA) T-score less than -2.5 standard deviations (SD) of young healthy adults (**Figure 110**). **Osteopenia** is a mild form of osteoporosis.

FIGURE 108

Disuse osteopenia on CT 5 weeks (A) and 15 weeks (B) after the initial injury in a 25-year-old woman with a sustentaculum tali fracture (arrows).

FIGURE 109

Hip fracture is the most dreaded complication of senile osteoporosis. Incomplete insufficiency fracture of the left femoral neck (arrow) in this 71-year-old man with osteoporosis was best shown on same-day MRI. A "hip" fracture denotes fracture of the proximal quarter of the femur.

FIGURE 110

DEXA in a 70-year-old woman shows osteoporosis in the spine and osteopenia in the femoral neck.

/ Osteomalacia

Occurring **after the cessation of growth**, osteomalacia, in contradistinction to rickets, does **not** predominantly involve growth plates. Inadequate or abnormal mineralisation of trabecular and cortical bone is observed. Patients typically present with insufficiency fractures,

formerly known as Looser zones (**Figure 111**). Large quantities of unmineralised osteoid are observed as indistinct/ill-defined trabeculae giving the impression of a “poor-quality” radiograph (**Figure 111**).

FIGURE 111

Looser zones along the bilateral medial femoral cortices, as well as in the right iliac bone (**arrowheads**), are present in this 74-year-old woman with osteomalacia. Large quantities of unmineralised osteoid are observed as indistinct/ill-defined trabeculae (especially in the diaphyses here).

<=> ATTENTION

Osteomalacia can also have an oncogenic aetiology (Figure 112). This occurs when tumours secrete substances that inhibit the ability of kidney to absorb phosphate.

FIGURE 112

Radiograph (A) and cross-sectional images from different MRI examinations of the hips (B), knees (C) and ankle (D). This 53-year-old man had hypophosphatemia secondary to a biopsy-proven phosphaturic mesenchymal tumour in the right proximal femur (arrowheads in A and B), resulting in osteomalacia. Note bilateral femoral neck insufficiency fractures (white arrows) and indistinct/ill-defined trabeculae (representing extensive unmineralised osteoid), giving the impression of a "poor-quality" radiograph. The patient had insufficiency fractures (yellow arrows) also around his both knees and one ankle.

Test Your Knowledge

/ Rickets

In rickets, the orderly development and mineralisation of growth plates is interrupted (**Figures 113 and 114**). Imaging findings are seen on the metaphyseal

side of the growth plate because of the concentration of unmineralized osteoid there (**Figure 113**).

FIGURE 113

Metaphyseal widening, cupping and fraying in the distal radius and ulna (**ellipse**) of a 15-month-old girl with rickets (**A**) resolved after treatment (**B**).

FIGURE 114

Rachitic rosary (**arrowheads** in **A**) denoting rib widening at the costochondral junctions in a 16-month-old girl with rickets resolved after treatment (**B**). Note bowing deformity of the lower extremities with metaphyseal flaring and fraying before treatment (**C**).

/ Renal Osteodystrophy

Renal osteodystrophy encompasses findings seen in the setting of **chronic renal insufficiency**. Among these are findings of osteomalacia (and rickets in children) and secondary hyperparathyroidism (**Figures 115 and 116**).

Skeletal imaging findings in osteomalacia/rickets and hyperparathyroidism are **independent from the aetiology** of these three conditions.

FIGURE 115

This 50-year-old man with chronic renal insufficiency and secondary hyperparathyroidism has subperiosteal bone resorption (**arrows**) at the radial aspects of the second and third middle phalanges and subchondral resorption (**dashed arrows**) in bilateral sacroiliac joints resulting in pseudo-widening. Note also acro-osteolysis in the second distal phalangeal tuft (**arrowhead**) and extensive vascular calcifications along fingers.

<=> ATTENTION

Radiologic findings of bone resorption are seen in hyperparathyroidism regardless of primary, secondary or tertiary type

FIGURE 116

Subtendinous bone resorption (**arrows**) at the insertion sites of gluteus medius, minimus and hamstring tendons and trabecular paucity (**A and B**) because of cancellous bone resorption (**B** is an edge-on radiograph of the skull).

/ Renal Osteodystrophy: An Overlap of Osteomalacia/Rickets and Hyperparathyroidism

- Although findings in osteomalacia/rickets and hyperparathyroidism **tend to overlap**, radiographic findings of hyperparathyroidism predominate in adults, whereas those of rickets are in the foreground in children.
- The **"rugger jersey spine"** appearance (named after the pattern of horizontal stripes on jerseys worn by rugby players), denoting alternating bands of sclerosis along the vertebral body endplates and areas of lucency centrally is a characteristic feature of secondary hyperparathyroidism seen in renal osteodystrophy (Figure 117).
- Soft tissue mineralisation** (in the form of vascular calcifications, chondrocalcinosis and tumoral calcinosis) is a characteristic feature of renal osteodystrophy (Figure 118).
- Parathyroid adenomas** are seen in the primary and tertiary forms of hyperparathyroidism. Ultrasonography is used to detect parathyroid adenomas (Figure 119).

FIGURE 117

"Rugger jersey spine" appearance in a 55-year-old woman with end stage renal disease.

FIGURE 118

Soft tissue calcifications (arrows) in a 50-year-old man with chronic renal failure.

FIGURE 119

Ultrasonography (transverse image) shows a parathyroid adenoma (arrow) in a 36-year-old woman. Right lobe of the thyroid gland (R), right common carotid artery (CCA), trachea (T).

Test Your Knowledge

Several examples of the numerous developmental abnormalities that can involve the musculoskeletal system are:

- / Scoliosis (one of the etiologic factors in scoliosis is developmental dysplasia)
- / Developmental dysplasia of the hip
- / Femoral trochlear hypoplasia/dysplasia
- / Glenohumeral dysplasia

Radiology not only brings diagnostic clues to developmental abnormalities but also provides information regarding the severity, outcome assessment and management follow-up of these conditions. Angular, point-to-point or projectional distance measurements on radiologic images are used for acquiring such information.

/ Imaging in Scoliosis

Developmental dysplasia is only one of the causes of scoliosis, the most common type of which (i.e., adolescent idiopathic scoliosis, not shown here) remains

of unknown aetiology. Radiographs, CT and MRI are widely used for the diagnosis and treatment planning, as well as follow-up of scoliosis (Figure 120).

FIGURE 120

Radiographs (1), CT (2, 3, 5) and MRI (4, 6, 7) show scoliosis (1) and associated abnormalities, such as hemivertebra, block vertebra, butterfly vertebra (2–4), diastematomyelia (5, 6), tethered cord and syringomyelia (7) and caudal regression syndrome (7).

/ Imaging in Developmental Dysplasia of the Hip (DDH)

Ultrasonography is an excellent tool in screening for developmental dysplasia of the hip (DDH), which is recommended to take place as early as

possible – but no later than the first six weeks after delivery (**Figure 121**). If untreated, DDH can progress to early-onset hip osteoarthritis (**Figure 122**).

FIGURE 121

A radiologist performs screening US in a newborn baby. Coronal plane US images in two different newborn babies show a normal hip (**above**) and a decentered hip (**below**), where the acetabulum (**A**) is dysplastic and the femoral head (**asterisks**) is not within a properly developed acetabular fossa.

Ultrasonography images courtesy of Dr Konstantinos Chlapoutakis, Heraklion, Crete, Greece

FIGURE 122

Radiographs show an infant with DDH on the right side (**A**) and a 37-year-old woman with DDH on both sides (**B**). The woman developed early-onset osteoarthritis and had a total hip replacement four years later (**C**). MR-arthrography image of the same woman (**D**) shows a thickened acetabular labrum with a tear (**arrow**).

Test Your Knowledge

/ Take-Home Messages

- / Sufficient and relevant clinical information needs to be given to the radiologist by the referring clinician in order to provide the best service to the patient, which encompasses the validation or determination of the best imaging modality and technique and evaluation of the imaging study.
- / First-line diagnostic modality in musculoskeletal (MSK) imaging is radiography.
- / Computed tomography (CT) is usually reserved for the identification and better characterisation of some fractures, assessment of bone lesions in complex anatomic areas and estimation of the mineral load in gout.
- / In the MSK system, ultrasonography (US) is mainly used in the evaluation of superficial structures.
- / Magnetic resonance imaging (MRI) is an excellent tool for imaging soft tissues, joints and bone marrow—including occult fractures.
- / An algorithmic approach starting with the identification of joint space narrowing on radiographs is useful in many arthropathies.
- / After trauma, lipohaemarthrosis on imaging suggests that an intra-articular fracture is present.
- / Imaging closely reflects pathophysiology in osteomyelitis—but should not delay joint fluid aspiration and microbiologic assessment in suspected septic arthritis.
- / Location across the body and site within a bone are, along with the patient's age, the key determinants of a bone tumour.
